## ABSTRACT

**Background:** Biological sex can impact the pathogenesis and outcome of viral infection by modulating immune responses that control inflammation, antibody production, and tissue repair. Influenza B viruses (IBVs) are classified into B/Yamagata and B/Victoria lineages, which co-circulate during the influenza season with varying dominance. Epidemiological data show greater circulation and diseases caused by IBV in recent years, with higher hospitalization and mortality rate in males than females, especially in children and the elderly. Compared with influenza A viruses (IAVs), however, studies of IBV are still lacking.

**Methods:** We developed a mouse model to study the sex differences in the pathogenesis of IBV infection. Adult male and female C57BL/6 mice were intranasally infected with  $10^5$  TCID<sub>50</sub> units of the B/Brisbane/60/2008 (Victoria lineage), carrying the PB2 F406Y mutation that increases virulence in mice. Morbidity and mortality were monitored for 15 days. Lungs were harvested and homogenized at 1, 3, 5, and 7 days post infection (dpi) to characterize viral kinetics. Lungs, spleens and sera were collected at 3 and 7 dpi for cytokine quantification to analyze the innate immune response. Neutralizing antibody titers were also determined in sera collected at 21 dpi.

**Results:** Male mice experienced greater morbidity, i.e., had greater body mass loss and hypothermia, than females. Biological sex affected lung viral kinetics, in which males consistently had higher virus titers than females. Males showed aberrant innate responses in the lungs, with lower local induction of cytokines than females in the lungs at 3 dpi, but sustained inflammation at 7 dpi of IBV infection. Both males and females showed peripheral induction of cytokines in the spleen and sera at 3 dpi and to a stronger extent at 7dpi, with no sex differences observed. Neutralizing antibody titers were significantly lower in males than females at 21 dpi.

**Conclusion:** Taken together, these data suggest that males experience more severe disease than females following IBV infection. Impaired viral clearance combined with compromised innate and adaptive immune responses in males compared with females may contribute to worse IBV outcomes. The effects of biological sex on IBV pathogenesis and responses to vaccines should be explored in humans.

**Secondary Reader: Dr. Fengyi Wan**

## ACKNOWLEDGEMENT

I would like to express my deepest gratitude to my advisor, Dr. Sabra Klein, for her continuous mentorship and support during my graduate research. Thank you for providing me with abundant academic opportunities, as well as the professional guidance. I would like to thank Yishak Woldetsadik, for doing previous work, mentoring me patiently, and teaching me the techniques detailly. I would like to thank Rebecca Ursin, for keeping concerned with this project, sharing her thoughts, and providing help when I got into trouble. Thank you to my lab mates, Patrick Creisher, Santosh Dhakal, Han-Sol Park, Abhinaya Ganesan, Morgan Sherer, Henning Jacobsen, Christopher Caputo, and Janna Shapiro, for their encouragement, insights, and all the help. Thank you to Dr. Andrew Pekosz, Dr. Kim Davis and their lab members, for their inspirations during the joint lab meetings. I would also like to thank my secondary reader, Dr. Fengyi Wan, for his input and advice.

I thank my friends here and away, Xuetong, Haoran, Zhihao, Amy, Yuyan, and Elaine, for their listening, understanding, and the encouragement. Thank you to Yan, for your accompany during my hardest moment. Last but not least, I would like to thank my parents, for being my solid backing and my best friends, and always supporting me to pursue my goals.

# INTRODUCTION

## Overview of Influenza Viruses

Influenza viruses, including influenza A, B, C and D viruses, are in the *Orthomyxoviridae* family (**Table 1**). Respectively, they are the only species in Alphainfluenzavirus, Betainfluenzavirus, Gammainfluenzavirus and Deltainfluenzavirus genera. Influenza A Virus (IAV) has a variety of hosts, including avian, swine, and human. In contrast, humans are the only known host of Influenza B Virus (IBV). It has been reported sporadically that IBV can infect seals, but there is still no evidence of the transmission from seals to humans [1-4]. Despite the limited host range, IBV can cause severe disease that is comparable to IAV, which makes IBV a public health concern. Influenza C Virus (ICV) was first isolated from human throat washings in 1947 and classified as a new type of influenza by Francis *et al* in 1950 [5-7]. Serological studies showed that the antibodies to ICV were prevalent in adults, indicating possible childhood ICV infections [5, 8-10]. However, compared to IAV and IBV, ICV only induces mild symptoms, and is not a significant pathogen of seasonal influenza. Influenza D Virus (IDV) is a recently identified influenza virus, which mainly infects swine and cattle. In 2013, when IDV was first discovered, it was recognized as a novel strain of ICV [11]. Subsequently, IDV was characterized as a new species in the *Orthomyxoviridae* family in 2014[12]. To date, there are no reports of human-related IDV infection.

Influenza viruses are enveloped viruses with segmented, single stranded, negative sense RNA genome, which code for different functional proteins. Single-stranded RNAs (ssRNAs) are covered by Nucleocapsid Proteins (NP). The viral polymerase (P) subunits, PA, PB1 and PB2, are attached to the ribonucleoprotein (RNP) and essential for virus replication. IAV and IBV have 8 segments in the genome, while ICV and IDV have 7 segments (**Table 1**). These segments

are enveloped by the matrix protein (M1) covered with a lipid bilayer from the infected host cell, with glycoproteins protruding on the surface. The virions of IAV and IBV are indistinguishable under electron microscope, which are usually in spherical or filament shapes and have two types of glycoproteins, including hemagglutinin (HA) and neuraminidase (NA), on the surface, which are the major surface antigens of influenza virus. In IAV, M2 proteins lay on the matrix, whereas in IBV BM2 and NB proteins are the matrix proteins. Distinct from IAV and IBV, the virions of ICV and IDV are more pleomorphic. Filamentous structures are more common in ICV and IDV and they can form long cordlike structures on the surface of infected cells. Beyond that, the surface glycoproteins on ICV and IDV are organized in a hexagonal pattern and are only consist of hemagglutinin-esterase-fusion (HEF) proteins. Similar to IAV, there are CM2 proteins overlaying the matrix (**Table 1**).

The influenza viruses can be further divided according to the genetic and antigenic differences. In IAV, 18 subtypes of HA (H1 to H18) and 11 subtypes of NA (N1 to N11) have been identified. And IAVs are divided into a variety of subtypes based on their HA and NA subtypes, for example, H1N1 and H7N9. In contrast, IBVs are only divided into two lineages, namely Yamagata and Victoria, by the sequence and antigenicity of HA [13]. ICV and IDV, which have HEF, instead of HA and NA, as the surface antigenic proteins, are further typed into lineages according to HEF. At present, there are six known lineages of ICV and four known lineages of IDV [14, 15].

The genomes of all influenza viruses are segmented ssRNAs. RNA virus polymerase lacks the activity of proofreading, resulting in an error-prone replication[16]. Therefore, HA proteins are of great variance with a high mutation rate. Under the immune pressure from the host immune response, these mutations can be selected and accumulated, leading to minor

changes on the antigen, termed antigenic drift. The variance of antigen can also be developed by reassortment, termed antigenic shift, which takes advantage of the segmented genome. When two different strains of influenza virus infect a same cell simultaneously, their genome segments can mix up and form a new strain with distinct characteristics. Antigenic shift frequently occurs in IAV, because IAV has been adapted to aquatic avian, which serves as a gene pool for IAV evolution. Antigenic shift of IAV usually induces influenza outbreaks. IBV also undergoes antigenic drifts and antigenic shifts. Evidence shows that antigenic shifts are of more importance in the evolution of IBV[17, 18]. However, the evolution rate is much slower than IAV because with limited animal reservoir, IBV lacks non-human gene pool [18, 19]. Within a type of influenza, the reassortment can occur within a lineage or between lineages[20]. Intertypical reassortment between influenza viruses has not been reported, which can be attributed to the incompatible packaging signals in different types of influenza virus [21].

Only IAV and IBV induce severe diseases in humans and are of epidemiologic interest. Historically, there have been four influenza pandemics: 1918 H1N1, 1957 H2N2, 1968 H3N2, and 2009 H1N1; all were caused by IAV substrains [22]. The pandemic is partially attributed to the fast evolution rate of IAV. The antigenic shifts lead to significant change in the surface antigens (HA and/or NA). Because humans are immunologically naïve to the new antigen, the novel IAV strain can readily infect and replicate in the host cells, often with greater transmissibility and virulence than seasonal strains, contributing to defining these as pandemic strains. The pandemic IAV strain will continue to circulate worldwide, undergoing antigenic drift, and eventually becoming a seasonal strain of IAV [23, 24]. IBV, which has limited hosts and thereby lower evolution rate, is not known to cause pandemics, while it co-circulates with IAV to cause seasonal influenza and can induce severe disease, similar to IAV. The receptors of

the two lineages of IBV are different (**Table 2**). Victoria lineage viruses recognize the Sialyl  $\alpha$ -2,3 Galactose as well as the Sialyl  $\alpha$ -2,6 Galactose, while Yamagata lineage viruses only recognize the Sialyl  $\alpha$ -2,6 Galactose. The difference in receptor binding may partially explain the epidemiological differences present between the two lineages. Generally, younger people are more susceptible to Victoria lineage viruses, with peak cases in individuals below 10 years of age. In contrast, the age distribution of disease caused by Yamagata lineage viruses peak among individuals younger than 10 years of age and again among middle-aged adults [25, 26]. Victoria lineage induces more severe disease and greater hospitalization rates than Yamagata lineage viruses [27]. Compared with Yamagata lineage viruses, the transmission of Victoria lineage viruses is more sustained within a region [26]. The circulating IAVs and IBVs, influenza-associated hospitalizations and mortalities are under continuous surveillance by the Centers of Disease Control and Prevention (CDC) in the United States as well as in other countries. Seasonal influenza is a substantial health burden in humans. As is estimated by World Health Organization (WHO), each year globally, seasonal influenza results in 3-5 millions of severe cases and 290 000-650 000 deaths due to respiratory diseases[28]. Aside from IAV, which is drawing a lot of attention, IBV is causing greater circulation and diseases in recent years[25, 29]. In 2019-20 season, 61.7% of pediatric mortality was caused by IBV[30]. Therefore, it is of great value and indispensable to have comprehensive understanding of IAV and IBV to control the influenza transmission and infection more efficiently.

### **The Life Cycle of Influenza A Viruses**

After invading into host organism, the HA of IAVs bind to the sialyl-galactose residues on the surface of host cells, primarily respiratory epithelial cells. Sialic acid linked to either the 3' carbon or 6' carbon of the galactose can be recognized by influenza HA, namely Sialyl  $\alpha$ -2,3

Gal and Sialyl  $\alpha$ -2,6 Gal. Sialyl  $\alpha$ -2,3 Gal is regarded as the avian receptor and Sialyl  $\alpha$ -2,6 Gal is regarded as the human receptor of influenza viruses, as avian influenza viruses preferentially bind the Sialyl  $\alpha$ -2,3 Gal and human influenza viruses preferentially bind the Sialyl  $\alpha$ -2,6 Gal [31, 32]. Sialyl  $\alpha$ -2,3 Gal is found in the avian intestinal epithelial cells, where avian influenza viruses replicate in their reservoir hosts [33, 34]. The two types of sialic acids, however, are present in human airways. Epithelial cells in the upper respiratory tract, including the trachea and bronchi, mainly express Sialyl  $\alpha$ -2,6 Gal, while Sialyl  $\alpha$ -2,3 Gal is enriched in the lower respiratory track, primarily in alveolar cells [35]. The different distribution of sialic acid receptors contributes to the host specificity of influenza viruses. Both the avian Sialyl  $\alpha$ -2,3 Gal and the human Sialyl  $\alpha$ -2,6 Gal present in the swine trachea [34], which is why swine serve as a mixing vessel for the reassortment of avian influenza virus and human influenza virus. New variants of IAVs, including the 2009 H1N1 pandemic strain are derived from swine. When avian IAVs develop the ability to bind the Sialyl  $\alpha$ -2,6 Gal by reassortment, these viruses can infect humans and cause serious epidemic and even pandemic levels of transmission.

After the binding of influenza HA to the Sialyl-galactose residue, the virus is engulfed in an endosome and a series of structural and chemical changes are initiated. First, host protease cleaves the HA at R329 and 1G into a fusion-competent form [36]. Virus acidification, driven by M2 ion channels, provides a low pH environment, which allows the HA to expose the fusogenic peptide [36, 37]. Fusogenic HA mediates the fusion of viral capsid and the endosomal membrane. The viral ribonucleoproteins (vRNPs) enter the host cell cytoplasm through the fusion pore, where the vRNP usurps the nuclear import machinery of the host cell to enter the nucleus [38].

The single-stranded negative-sense RNA segments of the influenza genome are the templates both for the viral mRNA transcription and for the synthesis of complementary RNA (cRNA), which serves as the replication template to produce multiple vRNAs. The biochemical process of transcription and replication are distinct (**Table 3**). Transcription occurs prior to replication, which is initiated by the binding of viral polymerase (vPol) to the host eukaryotic polymerase II (ePol II) and is primed by the capped host pre-mRNA segments [39]. The host pre-mRNA primer is caught by PB2 and then cleaved by PA[40]. Viral mRNA is synthesized by PB1 using vRNA as the template, which then seizes the host ribosomes to express viral proteins. Replication is a two-step process and is primer-independent [40]: 1) cRNA is synthesized by PB1 and 2) new vRNA synthesis uses cRNA as the template. The rate of replication is much slower than the transcription [41].

After vRNA synthesis, PB1, PB2, PA, and NP binds to the vRNA to form the vRNP in the host nucleus. Similar to the import, the vRNP exploits the host nucleus export protein, namely exportin-1, to migrate into the host cytoplasm [38]. Surface proteins, including NA, HA, and M2, are inserted into the plasma membrane. The virion is assembled at the plasma membrane and nucleated driven by M1 proteins. Finally, NA cleaves the sialic acid from the glycoproteins, releasing the budding virus from the host cell.

### **The Innate immune responses to IAV infection**

The innate immune responses that recognize and respond to IAVs are critical for antiviral immunity. Pathogen-associated molecular patterns (PAMPs) are recognized by pattern-recognition receptors (PRRs), including surface PRRs, such as Toll-like receptors (TLRs) and cytosolic PRRs [42, 43]. For IAVs, TLR3 and TLR7 are the major functional surface PRRs. TLR3 recognizes dsRNA in the endosome of IAV infected cells, providing signals to restrict

viral replication and prime the adjacent cells, and expressing chemokines to recruit innate and adaptive immune cells[44-46]. TLR7 recognizes the ssRNA genomes contained in IAV virions, activates nuclear factor- $\kappa$ B (NF- $\kappa$ B) and IFN-regulatory factor 7 (IRF7) via MyD88 signaling to express type I interferons (IFNs), pro-inflammatory cytokines, and multifunctional interleukin 12 (IL-12). Type I IFNs can directly interfere the viral replication, prime the adjacent cells, and enhance the cell-mediated immunity[47, 48]. Pro-inflammatory cytokines, including tumor necrosis factor (TNF) and IL-6, improve the immune cell function, but also result in the systemic symptoms of influenza[49]. IL-12 is the key factor to induce the T<sub>H</sub>1 responses[50]. It also promotes natural killer (NK) cells and T cells to release type II IFN (IFN $\gamma$ ), which serves as a non-specific activator for many immune cells [50] (**Table 4**). TLR7 also plays an important role in antibody production [51, 52]. TLR7 deficiency leads to compromised early-B-cell response and lower level of HA-specific antibody production [53]. Administration of TLR7 agonists facilitate more robust immune responses to IAV infection in mice [54].

Other PRRs, including retinoic acid-inducible gene I (RIG-I) and Nucleotide-binding oligomerization domain, Leucine rich Repeat and Pyrin domain containing Proteins (NLRPs) have roles in cytosolic PAMP recognition. RIG-I recognizes the replicated viral ssRNA bearing 5'-triphosphate[55-57], activating NF- $\kappa$ B and IRF3 via mitochondrial antiviral-signaling (MAVS) [58]. IAV infection also stimulates the NLRP3 oligomerization. Oligomerized NLRP3 recruits apoptosis-associated speck-like protein containing a CARD (ASC) and Caspase 1 to form an NLRP3 inflammasome, leading to caspase-1 activation and pro-inflammatory IL-1 $\beta$  and IL-18 secretion [59, 60]. Evidence also shows that ASC and Caspase 1 are indispensable in developing the adaptive immune responses against IAV infection[61].

Innate immune system reacts rapidly after the exposure to IAV and leads to early signs of influenza infection, including feverishness, fatigue, headaches, and myalgias, which are induced by pro-inflammatory cytokines [62]. During influenza infection, cytokines help with the antiviral process either by interfering viral replication or by enhancing the cell-mediated and/or humoral immune responses (**Table 4**). However, the rapid and excess production of cytokines leads to cytokine storm, which is the pathogenic sin for acute respiratory syndrome, tissue damages, and organ dysfunctions. Pro-inflammatory cytokines stand in the eye of the storm. TNF plays a key role in the cytokine storm, contributing to the morbidity of IAV infection by inducing hyperactive inflammation, tissue damage, and lung consolidation[63-65]. IFNs activate the IFN-induced gene expression, which is indispensable for IAV clearance, nevertheless, excessive IFN signaling causes uncontrolled inflammation and irreversible lung tissue damage[66-69]. IL-1 and IL-18, which are the downstream products of NLRP3 inflammasome, are also responsible for the acute pulmonary immunopathology[70, 71]. However, IL-6 serves as a protective factor in the hyperinflammation by producing neutrophil survival and reducing the lung pathology[72, 73]. In addition, excessive chemokines can recruit superfluous immune cells to the site of infection, which exacerbates the detrimental inflammation[74].

During IAV infection, the non-specific innate immunity is first initiated via PAMP-PRR recognition, priming the uninfected cells and inducing the specific and more efficient adaptive immunity. Innate immune responses play an important role in the early stage of infection to interfere viral replication and assist with viral clearance. However, the inflammation induced by innate immune responses contributes to immunopathology, and even can result in the mortality of influenza.

### **The Adaptive Immune Responses to IAV Infection**

The adaptive immune response typically takes 5-7 days to develop, providing a highly specific and efficient effect to restrict viral replication, clear the viruses, and develop memory to protect from re-infection. The humoral response is predominated by HA-specific antibody and NA-specific antibody. Anti-HA antibodies typically bind to the head domain of HA, which contains the receptor-binding site and is variable between IAV strains[75, 76]. These antibodies neutralize the viral infection either by blocking the IAV entry to the cell or by inducing the Fc receptor-mediated phagocytosis[77]. Some HA specific antibodies that bind to the HA stem domain, which is the conserved region, also have the protective effect via neutralizing viruses and inducing antibody-dependent cell-mediated cytotoxicity (ADCC) [78-80]. HA stem-binding antibodies are the major components of cross-reactive antibodies against influenza, and they have a broad-spectrum protection across IAV strains and even across both IAV and IBV [81-85]. Anti-NA antibodies also have protection against influenza infection by inhibiting the enzymatic activity. NA active site-binding antibodies that broadly neutralize multiple different IAV and IBV strains [86, 87]. Influenza infection also induces antibodies against NP, matrix proteins, and other virion components [75, 88-90]. Antibody responses are mount within 1-2 weeks after influenza infection. IgG is the dominant subtype of protective influenza-specific antibodies in lungs and serum, while IgA plays a more important role in mucosal protection at the entrance of infection, i.e., the respiratory tract [91, 92]. The antibody protection induced by natural infection of influenza can last for decades [75].

The clearance of infected cells requires a cellular response, mediated by CD4<sup>+</sup> T cells and CD8<sup>+</sup> T cells. Dendritic cells process and present the exogenous and endogenous influenza virus antigens in the class I and class II major histocompatibility complex (MHC) molecules to CD8<sup>+</sup> and CD4<sup>+</sup> T cells, respectively. CD4<sup>+</sup> T cells recognize the influenza epitope in the

context of class II MHC, further differentiating to Th1 cells to protect against viral infection [93]. Th1 cells produce IFN- $\gamma$  which has the antiviral activity and can activate macrophages [94, 95]. IAV-activated CD4<sup>+</sup> T cells also produce IL-2 to stimulate CD8<sup>+</sup> T cell proliferation and differentiation [96]. Activated and armed CD8<sup>+</sup> T cells, also called cytotoxic T cells (CTLs), recognize the influenza peptide presented in class I MHC. CTLs can either directly kill the infected cell via cytolysis using preformed perforin and granzymes or induce apoptosis via Fas/FasL interaction[97]. Evidence shows that CTLs are more cross-reactive to different influenza strains compared to the antibodies[98]. However, the memory pool of CTLs that recognize IAVs contract within a few years, and the longevity of T cell memory after influenza infection is still unclear [99, 100]. Besides, dysregulated CTL can also accelerate the pulmonary immunopathology via its cytotoxic activity or pro-inflammatory cytokine secretion[101, 102].

Adaptive immunity is not initiated immediately after infection, but it is the most powerful defense. Neutralizing antibodies, which are highly specific to a certain IAV epitope, interfere the viral life cycle to slow down the spread of virions. CD4<sup>+</sup> T cells predominantly differentiate to Th1 cells during IAV infection, providing sufficient IFN- $\gamma$  to impede viral replication. Meanwhile, CD8<sup>+</sup> T cells are activated and armed to specifically clear the IAV infected cells by direct contact and the cytotoxicity. In addition, adaptive immunity can develop long-term memories to prepare for the next exposure to the identical pathogen. However, the adaptive immune responses need to be well-regulated to avoid the drastic tissue damage.

### **Animal Models to Study Influenza Pathogenesis**

The pathogenesis of IAV infection has been characterized in various mammalian animal models, including mice, rats, guinea pigs, ferrets, hamsters, and rhesus macaques [103]. Mice are the most commonly used model, and inbred mouse strains, including BALB/C, C57BL/6, and

DBA/2, are frequently used to study IAV pathogenesis via intranasal infection. DBA/2J mice are more susceptible to IAV infection compared to BALB/C and C57BL/6 mice [104, 105].

However, animal models for IBV pathogenesis are lacking because of the limited host range of IBV. Mice and ferrets have been used for IBV pathogenic models[106-108]. IBV must be adapted by serial passaging or inducing mutation to increase the infectivity in non-host animals[106-108].

### **Sex Difference in the Response to Influenza Infection**

Epidemiological evidence shows age-stratified sex differences in the morbidity and mortality of IAV infection both in pandemics and seasonal epidemics [109-113]. In children, the confirmed cases are significantly higher in boys than girls [111, 112]. While in adults, the male to female ratio (MFR) decreases and even reverses [111]. In the mouse models of IAV infection, females have greater morbidity and slower recovery than males [114-116]. This female bias in IAV disease pathogenesis is caused by sex steroid hormone-mediated greater inflammation and reduced activation of repair pathways [114-118]. For example, greater production of amphiregulin and testosterone production in males have been shown to independently protect male mice in H1N1 infection [114]. While amphiregulin promotes repair of damaged tissue caused by infection and immune-activation, testosterone dampens inflammation [117]. In female mice, infection with IAV disrupts their reproductive cycle and administration of estradiol, estriol, or progesterone can suppress the inflammatory response to protect them from severe pathogenesis [115, 118, 119]. Females produce more neutralizing antibodies, and the total antibody response against IAV is stronger in females than in males, which is also mediated by estradiol in female mice [116, 120]. While progesterone treatment reduces the adaptive immune

responses in female mice, compromising the protection from re-exposure[118]. And the cross protection of humoral immune response is greater in females compared to males [116].

In IBV, sex differences in disease pathogenesis are age dependent. Generally, males are less likely to be infected with IBV [121]. In children, however, boys have a higher frequency of IBV infections than girls [122]. The hospitalization rate also is higher in males than in females, except for among young adults, age 18-39, in which females experience greater disease than males [25, 112, 123]. Females also tend to have a lower mortality from IBV infection [124].

Comparing to IAV, there are fewer pathogenic studies of IBV infection due to the lack of suitable animal models. Recent study in female mice found that IBV infection induces severe diseases and decreases concentrations of progesterone and estradiol during pregnancy, suggesting that sex hormone can be disturbed by IBV infection [125]. Unpublished data from our collaborator Dr. Daniel Perez show greater morbidity in the male DBA/2J mice compared to the females infected with mouse-adapted B/Brisbane/60/2008 (Victoria lineage), which is different from IAV infection (see above).

Therefore, to better understand the effect of biological sex on IBV infection, we established a pathogenetic model in male and female C57BL/6 mice. We compared the morbidity, lung viral kinetics, cytokine responses, and antibody production between male and female mice. Results were also compared with the published corresponding data of IAV.

## METHODS

### Animals

Adult (8-12 weeks) male and female C57BL/6 mice were purchased from Charles River Laboratories. All animals were housed at up to 5 mice per microisolator cage under standard biosafety level 2 housing conditions, with food and water provided *ad libitum*. All experiments were performed in compliance with the standards outlined in the National Research Council's Guide to the Care and Use of Laboratory Animals. All animal procedures were approved by the Johns Hopkins Animal Care and Use Committee (MO18H250). All efforts were made to minimize animal suffering.

### Virus

B/Brisbane/60/2008 with PB2 F406Y mutation (mt-B/Bris) virus was used in this study for infection and antibody titration. PB2 F406Y mutation was induced to B/Brisbane/60/2008 virus by Dr. Daniel Perez to enhance the pathogenesis in mice. The working stock was generated by infecting Madin-Darby Canine Kidney (MDCK) cells at a multiplicity of infection (MOI) of 0.01 and the infected cell supernatant was collected, centrifuged, and the virus containing supernatant was collected. The quantity of viruses is determined by units of tissue culture infectious dose (TCID<sub>50</sub>).

### Animal infection and processing

Mice were anesthetized with ketamine (80mg/kg)/ xylazine (13mg/kg) cocktail injected intraperitoneally and inoculated intranasally with 10<sup>4</sup> and 10<sup>5</sup> TCID<sub>50</sub> units of B/Brisbane/60/2008 in 30uL of the virus in Dulbecco's modified Eagles Medium (DMEM). For morbidity study, body mass and rectal temperature changes were daily recorded up to 14 days

post infection (dpi). For time course experiments, mice were randomly assigned to be euthanized at 1, 3, 5, and 7 dpi. Mice were anesthetized using ketamine–xylazine cocktail before retrobulbar bleeding. Blood was collected into heparinized tubes and was centrifuged to separated plasma. Plasma was stored at -80°C and used to measure cytokines. Left lung and spleen were collected, snap-frozen and stored at -80°C. Right lung lobes were inflated and fixed with zinc-buffered formalin (Z-fix, Anatech, MI, USA) under a constant pressure of 25 cmH<sub>2</sub>O for at least 24 hours. Plasma was also collected at 21 dpi to measure the antibodies.

### **Lung virus titration**

Left lungs were homogenized in 500ul of serum-free DMEM. Infectious viral particles in the supernatants were detected using TCID<sub>50</sub> assay. Lung samples were 10-fold serial-diluted and transferred into 96-well tissue-culture plates in six replicates to infect a confluent monolayer of MDCK cells. Plates were incubated at 32°C for 6 days, fixed with 4% formaldehyde, and stained with naphthol blue black. Units of TCID<sub>50</sub> were calculated based on the cytopathic effects (CPE) of influenza B virus.

### **Detection of cytokines and chemokines**

Left lungs and spleens were homogenized in 500ul of serum-free DMEM, followed by centrifugation to remove the cellular debris. Cytokines and chemokines in lungs, spleens, and sera were measured using the Immune Monitoring 48-Plex Mouse ProcartaPlex™ Panel on Curiox DA-Bead DropArray platform according to the manufacturer's instructions. The following analytes were quantified: granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), macrophage colony-stimulating factor (M-CSF), IFN- $\alpha$ , IFN- $\gamma$ , IL-1 $\alpha$ , IL-1 $\beta$ , IL-2, IL-2R, IL-3, IL-4, IL-5, IL-6, IL-7, IL-7Ra, IL-9, IL-10, IL-12p70, IL-13, IL-15, IL-17A, IL-18, IL-19, IL-22, IL-23, IL-25, IL-27, IL-28, IL-31, IL-

33, IL-33R, Leukemia inhibitory factor (LIF), CXCL1, CXCL2, CXCL5, CXCL10, CCL2, CCL3, CCL4, CCL5, CCL7, CCL11, TNF $\alpha$ , receptor activator of nuclear factor kappa-B ligand (RANKL), B-cell activating factor (BAFF), Betacellulin, vascular endothelial growth factor (VEGF)-A, and Leptin. For analyses, the concentration of following analytes remained below the limit of detection at all time points and were excluded: IL-2R, IL-9, IL-19, IL-31, CXCL10, and Leptin in lungs, IL-9 in spleens, and IL-2, IL-3, IL-4, IL-7Ra, IL-13, IL-22, IL-27, LIF, Betacellulin, CXCL5, CCL3, and CCL5 in sera. Cytokine fold changes, i.e., the raw concentrations (pg/ml) relative to the geometric mean concentrations (pg/ml) of mock infected samples, were calculated to control for baseline sex differences.

### **Detection of neutralizing antibodies**

Plasma neutralizing antibodies were detected using microneutralization assay with MDCK cells. Plasma samples were inactivated at 56°C for 30 minutes and 2-fold serial-diluted to neutralize 50 TCID<sub>50</sub> of influenza B virus for 1 hour at room temperature. The plasma-virus mixture was transferred into 96-well tissue-culture plates in quadruplicates and incubated for 24 hours at 32°C to infect MDCK cells. Following incubation, cell culture media were changed to remove the inoculum. Plates were incubated at 32°C for another 5 days, fixed with 4% formaldehyde, and stained with naphthol blue black. The neutralizing antibody titers were calculated as the highest plasma dilution that eliminates the CPE in at least 50% of the wells.

### **Statistical analyses**

Longitudinal morbidity measures, including body mass and temperature, were analyzed with repeated-measures two-way ANOVAs. Longitudinal measures with unmatched samples, including lung virus titers and cytokine fold changes, were analyzed using unmatched two-way

ANOVAs with Bonferroni post hoc correction for multiple comparisons. Single time point neutralizing antibody titers were analyzed using Student t-tests. Comparisons were considered statistically significant at  $p < 0.05$ . All statistical analyses were conducted using Prism 9.

## RESULTS

### **Morbidity from B/Brisbane/60/2008 is greater in males than females**

To investigate sex differences in the outcome of IBV infection, adult male and female C57BL/6 mice were inoculated with  $10^4$  or  $10^5$  TCID<sub>50</sub> of B/Brisbane/60/2008 and were monitored for 15 days for changes in body mass and rectal temperature as well as death (**Figure 1A**). Infection with  $10^4$  TCID<sub>50</sub> did not cause observable disease in either males or females, while infection with  $10^5$  TCID<sub>50</sub> resulted in pathogenesis in both sexes (**Figure 2A and 2B**). Body mass loss was observed after 4-5 days post infection (dpi), and recovery began at 6-7 dpi (**Figure 2A**). Male mice experienced greater morbidity, i.e., had greater body mass loss and [hypothermia](#), compared to the females (**Figure 2A and 2B**,  $p < 0.05$ ). No mortality was observed in female mice, while one male died at 8 dpi among mice infected with  $10^5$  TCID<sub>50</sub>.

### **Male mice have greater titers of B/Brisbane virus in lungs than female mice**

To determine if male biased disease severity was caused by a reduced ability of males to control virus replication, lungs were collected at 1, 3, 5, or 7 dpi for virus titration (**Figure 1B**). A significant main effect of sex was observed, in which lung viral titers peaked in 3 and 5 days after IBV infection, with a consistent trend that males had greater titers than females (**Figure 2C**,  $p < 0.05$ ). There also was a significant interaction between sex and dpi, in which at 5 dpi, the difference of IBV titers in lungs was maximized (**Figure 2C**,  $p < 0.05$ ). These data illustrate that that males compared with females had a reduced ability to control virus replication.

### **Male mice developed an aberrant local inflammatory response**

To understand the possible factors leading to the male bias in pathogenesis and viral clearance, pulmonary, splenic, and peripheral cytokine concentrations were measured at 3 (i.e.,

during peak virus replication) and 7 (i.e., after virus clearance) dpi. Because there can be baseline sex differences associated with instillation of vehicle into the lungs [115], sex difference in the baseline concentrations of cytokines were controlled by analyzing the fold change relative to mock infected male or female mice. In response to B/Brisbane infection, both males and females showed systemic immune activation during the first week after IBV infection, as is reflected in the increased expression of IFN- $\alpha$ , IFN- $\gamma$ , IL-12p70, IL-18, CXCL2, and CXCL5 in the spleen and IFN- $\alpha$ , IL-1 $\beta$ , IL-6, and IL-18 in serum (**Figure 3, Figure 4, and Supplemental Table 1, Supplemental Table 2**). Peripheral induction of cytokines showed rare sex differences. In the spleen, females expressed greater IL-28 than males at 3 dpi, while males expressed greater IL-23 and CXCL10 at 7 dpi (**Figure 3**). In the serum, significant sex differences were only observed at 7 dpi, with greater expression of IL-9, IL-33, CCL7, and CCL11 in females (**Figure 4**).

There were greater differences between males and females at the site of infection (**Figure 5**). At 3 dpi, females presented with greater concentrations of IL-1 $\alpha$ , IL-1 $\beta$ , and IL-12p70 in lungs than males, suggesting that females had a more rapid local innate response during peak virus replication (**Figure 6A, 6B, and 6C,  $p < 0.05$** ). In contrast, at 7 dpi, the pulmonary concentrations of IFN- $\gamma$ , IL-3, IL-6, CCL2, CCL3, and CCL4, were significantly greater in lungs from male than female mice (**Figure 6D, 6E, 6F, 6I, 6J, and 6K,  $p < 0.05$** ). In addition, there was a trend in IFN- $\alpha$  and TNF $\alpha$  that showed greater inductions in females at 3 dpi but in males at 7 dpi (**Figure 6M and 6N**). Taken together, these data suggest that while both males and females experience appropriate immune activation following infection, females develop more rapid cytokine responses in the presence of virus and males sustain cytokine responses after virus has been cleared.

**During the recovery phase of IBV infection, females produced greater neutralizing antibody titers than males**

Recovery from IBV infection requires induction of adaptive immune responses, which contribute to viral clearance and memory responses that protect against re-infection. To evaluate sex differences in the humoral response following IBV infection, serum was collected at 21 dpi from IBV-infected male and female mice (**Figure 1A**). After B/Brisbane infection, female mice produced significantly greater neutralizing antibody titers than male mice (**Figure 7**,  $p < 0.05$ ). The greater neutralizing antibody titers suggest stronger humoral responses in females, which may contribute to the better outcome in females during the primary IBV infection, and provide more efficient protection from the re-exposure to B/Brisbane virus in females than males.

## DISCUSSION

In this study, we established a IBV pathogenesis model using adult C57BL/6 mice. Sex differences were observed, with worse symptoms and greater virus replication and slower clearance of virus from the lungs in male mice. Male mice also had slower pulmonary induction of cytokines in the lungs during peak virus replication, but then sustained and even elevated pulmonary cytokine responses after virus had been cleared from the lungs. Females also produced greater antiviral antibody responses than males, which could be significant for protection following re-infection.

Sex biases are observed among many different host species ranging from mice to humans and in response to many pathogens [126]. Generally, the susceptibility to infection is greater for males than females, which could be explained by the sex disparities in gene expression, immune responses, and behavior [127]. Considerable evidence shows that factors associated with biological sex, including sex steroid and growth factor modulation of immune responses, affect IAV pathogenesis (**Table 5**). Sex steroids impact the pathogenesis and outcomes of viral infection by modulating inflammation, antibody production, or tissue repair. However, these mechanisms result in worse outcomes in females following IAV infection, whereas our study showed a male bias in IBV pathogenesis. Therefore, more comprehensive studies are necessary to understand the role of biological sex in the response to IBV infection.

In our study, after the infection of  $10^5$  TCID<sub>50</sub> of B/Brisbane/60/2008, male mice experienced significantly more severe disease than females. Remarkably, the outcomes of IAV infection are generally worse in reproductive aged adult females in both humans and mice, which is opposite to our observation in IBV infection [114, 115, 128, 129]. In fact, a number of studies from our laboratory using diverse H1N1 and H3N2 IAV viruses have shown that adult C57BL/6

female mice experience greater morbidity than male mice (Robinson et al. 2011, Lorenzo et al. 2011, Vermillion et al. 2018). Sex differences in the pathogenesis of IAV are not associated with differences in the ability to control virus replication, because sex differences in pulmonary infectious virus titers have not been observed [114, 115, 129]. Our IBV data, however, show a significant sex effect in pulmonary virus replication kinetics, with male lungs containing higher titers of virus than female lungs.

Innate responses to replicating virus are integral for control of viral infection. During peak viral replication, i.e. at 3 dpi, females had greater concentrations of IL-1 $\alpha$ , IL-1 $\beta$ , and IL-12, which are important for immune responses activation and modulation of T cell differentiation [93, 130-132]. At 7 dpi after B/Bris infection, when the virus had been cleared, males presented with significantly greater concentrations of IFN- $\gamma$ , IL-6, CCL2, CCL3, and CCL4 in lungs compared to females. Noticeably, IFN- $\gamma$ , IL-6, and CCL2 are higher in female lungs than in males after IAV infection [129, 133]. Therefore, the sex difference in the continuous production of IFN- $\gamma$ , IL-6, and CCL2 might be the direct reason for the sex-biased outcome. To test these hypotheses, IFN- $\gamma$  knockout male and female mice should be included in the future work, to see if the sex dimorphisms in viral clearance and in disease outcomes could be neutralized by IFN- $\gamma$  deficiency. IL-6 or CCL2 knockout mice would also help to interpret the mechanisms of sex-biased immunopathogenesis. IFN- $\alpha$  and TNF $\alpha$  also showed a trend in the induction, which was greater in females at 3 dpi, while in males at 7 dpi. The aberrant cytokine induction may result in compromised viral clearance and more severe tissue damage in males.

Successful recovery from influenza infection relies on the immune system to find a balance among antiviral defense, immunopathogenesis, and tissue repair. In our study, at 3 dpi after IBV infection, pro-inflammatory cytokines, including IL-1 $\beta$ , IL-6, and IFN- $\alpha$ , were

increased in serum of both sexes, inducing systematic symptoms such as hypothermia and fatigue[130, 134, 135]. Besides, these cytokines are essential for the activation of immune responses by modulating monocyte differentiation, activating adaptive responses, and promoting antibody isotype switching [73, 131, 136-138]. The antiviral function of IFN family is also important in defense against influenza virus [139]. In lungs, IFN- $\alpha$  and IFN- $\gamma$  were significantly induced to suppress viral replication at 3 dpi. Meanwhile, chemokines were elevated to attract the immune cells to the infection site. However, overproduction of pro-inflammatory cytokines and excessive cytotoxic effects from NK cells and CD8<sup>+</sup> T cells lead to tissue damage[102]. At the end of viral clearance, a downregulation on the expression of pro-inflammatory cytokines and chemokines is inevitable to avoid further damage. At 7 dpi, the levels of IFN- $\gamma$ , IL-6, and CCL2, CCL3, CCL4 in male mice were significantly higher than in female mice, resulting in worse symptoms and longer courses. Interestingly, although IL-6 causes tissue damage, it has been identified to suppress the hyper-inflammation[73]. Therefore, the elevation of IL-6 may serve as a signal for hyper-inflammation. During influenza pathogenesis, IL-12 and IL-33 have been shown to promote tissue repair. We observed higher level of IL-12 in female lungs at 3 dpi, and elevated IL-33 in female serums at 7 dpi, which may contribute to the faster recovery of females.

As IBV is causing greater circulation and diseases, prophylaxis for IBV needs more attention. Males tend to have lower antibody responses than females following influenza vaccination [140-143], which might be attributed to the sex disparity in the global gene expression in B cells [144]. In our study, females produced greater neutralizing antibody titers at 21 dpi after IBV infection, indicating poorer humoral responses to IBV antigens in males, which might be explained by the distinct process of B cell proliferation and differentiation in males and

females. In short, males have lower immunity to IBV antigens but suffer greater diseases from IBV infection. The effects of biological sex on IBV pathogenesis and vaccine responses in humans should be explored. Influenza vaccination rate in males, especially in children and elderly, should be taken seriously.

In summary, our data suggest that males experience more severe disease than females following IBV infection, which may result from impaired viral clearance and compromised innate and adaptive immune responses. To date, studies on IBV pathogenesis are still lacking, and there is no published data comparing male and female responses using animal models. Our study established a successful IBV pathogenic mouse model using mouse-adapted B/Brisbane virus (Victoria lineage) in adult male and female C57BL/6 mice. Other strains of IBV Yamagata lineage, and other mouse strains might be applied to repeat and compare. A comprehensive understanding of IBV pathogenesis in different sexes will help with more precise influenza prophylaxis and treatment. The mechanisms on how sex steroids and sex chromosomal genes regulate the responses to IBV require further investigation. Besides, this study only focused on the sex disparity in reproductive aged adult mice. Juvenile and aged mice should also be included to identify the age-sex interaction in future studies.

**Table 5.** The effect of sex associated factors on influenza pathogenesis.

<b>Factor</b>	<b>Type</b>	<b>Effect</b>	<b>Function</b>
<b>Amphiregulin</b>	Growth factor	Protective	Promote tissue repair
<b>Testosterone</b>	Sex steroid	Protective	Reduce inflammation
<b>Estradiol</b>	Sex steroid	Protective	Reduce inflammation; promote antibody production
<b>Estriol</b>	Sex steroid	Protective	Reduce inflammation
<b>Progesterone</b>	Sex steroid	Protective; harmful	Reduce inflammation; promote tissue repair; reduce adaptive responses

(A) Adult male and female C57BL/6 mice were intranasally inoculated with 30 $\mu$ l 10<sup>4</sup> or 10<sup>5</sup> TCID<sub>50</sub> of mouse-adapted B/Brisbane/60/2008 viruses. The mice were then monitored 15 days in body mass and rectal temperature. At 21 days post infection (dpi), mice were euthanized to collect blood for microneutralization assays (n = 10 or 20/group). (B) Adult male and female C57BL/6 mice were intranasally inoculated with 30 $\mu$ l 10<sup>5</sup> TCID<sub>50</sub> of mouse-adapted B/Brisbane/60/2008 viruses. The mice were euthanized at 1, 3, 5, or 7 dpi to collect lung samples for virus titration (n = 9-12/group). At 3 and 7 dpi, mice were euthanized to collect lung, spleen, and serum for cytokine quantification (n = 10-12/group).

**Figure 2: Morbidity and lung virus titers of B/Brisbane infected adult male and female C57BL/6 mice.**

Adult male and female C57BL/6 mice were intranasally inoculated with 30 $\mu$ l 10<sup>4</sup> or 10<sup>5</sup> TCID<sub>50</sub> of mouse-adapted B/Brisbane/60/2008 viruses. Loss of body mass (A) and rectal temperature (B) were measured for 15 days, as correlates of morbidity. Data represents Means  $\pm$  Standard Error of Mean from four groups (n=10 or 20/group). Infectious virus was measured in the lungs by

TCID<sub>50</sub> at 1, 3, 5, or 7 dpi (C; n = 9–12/group/time-point). Significant differences between males and females are denoted by asterisks (\*  $p < 0.05$ ).

**Figure 3: Cytokine fold change profile in spleens.**

Adult male and female C57BL/6 mice were intranasally inoculated with 30μl 10<sup>5</sup> TCID<sub>50</sub> of mouse-adapted B/Brisbane/60/2008 viruses (n = 10-12/group) or mock-infected (n = 9/group).

At 3 and 7 dpi, spleens were harvested and homogenized. The cell-free supernatants were used to quantify 48 cytokine analytes. The color gradient of heatmap (A) represents the log<sub>10</sub> fold change in splenic cytokine concentrations relative to respective mock-infected controls. The radar maps discriminate male and female differences at 3 dpi (B) and 7 dpi (C) in the log<sub>10</sub> fold change of splenic cytokine concentrations relative to respective mock-infected controls. Significant main effects of sex are denoted by asterisks (\*  $p < 0.05$ ). Significant differences between males and females at 3 dpi are denoted by diesis (‡  $p < 0.05$ ). Significant differences between males and females at 7 dpi are denoted by pound (#  $p < 0.05$ ).

**Figure 4: Cytokine fold change profile in sera.**

Adult male and female C57BL/6 mice were intranasally inoculated with 30μl 10<sup>5</sup> TCID<sub>50</sub> of mouse-adapted B/Brisbane/60/2008 viruses (n = 10-12/group) or mock-infected (n = 9/group).

At 3 and 7 dpi, blood was collected, and serum was separated to quantify 48 cytokine analytes.

The color gradient of heatmap (A) represents the log<sub>10</sub> fold change in serum cytokine concentrations relative to respective mock-infected controls. The radar maps discriminate male and female differences at 3 dpi (B) and 7 dpi (C) in the log<sub>10</sub> fold change of cytokine concentrations relative to respective mock-infected controls. Significant main effects of sex are denoted by asterisks (\*  $p < 0.05$ ). Significant differences between males and females at 3 dpi are

denoted by diesis ( $\ddagger p < 0.05$ ). Significant differences between males and females at 7 dpi are denoted by pound ( $\# p < 0.05$ ).

## Curriculum Vitae

Aihui Wang  
Baltimore, MD 21202  
443-333-3693  
awang88@jh.edu

### EDUCATION

---

**Johns Hopkins University, Bloomberg School of Public Health** Sep. 2019-Present  
• Sc.M. in Biochemistry and Molecular Biology

**Shanghai Jiao Tong University, School of Medicine** Sep. 2015-Jun. 2019  
• B.S. in Medical Laboratory Tech

### ACADEMIC EXPERIENCES

---

#### Research Experiences:

**Sex Differences in the Influenza B Virus (IBV) Pathogenesis** Jun. 2020-Present  
*Johns Hopkins University, Bloomberg School of Public Health*

*Advisor: Dr. Sabra Klein, Professor*

#### Contribution:

- Established mouse model of IBV, including conducting mLD50 tests, using morbidity and mortality
- Mastery of infection protocols for both mice (in vivo) and cell culture (in vitro), with analysis of virus titration and quantification in tissues and cells and optimization of protocols specific for IBV
- Mastery of animal handling, dissection, and tissue and blood collection techniques
- Utilization of basic microbiological and immunological assays including TCID50, ELISA, microneutralization, and cytokine multiplex assays

**Correlation Analysis of Vaginal Microbiome Diversity and Cervical Intraepithelial Neoplasia** Oct. 2018-Apr. 2019  
*Obstetrics and Gynecology Hospital of Fudan University, Clinical Lab*

*Advisor: Dr. Chunmei Ying, Chair*

#### Contribution:

- Collected and stored clinical vaginal swab specimens
- Analyzed the diversity data of vaginal microbiome from 32 cases; compared alpha and beta diversity between different levels of cervical intraepithelial neoplasia

**Method Development for the Detection of a MyD88 Point Mutation using allele specific-PCR** Jun. 2017-Jul. 2017  
*Shanghai Ruijin Hospital*

*Advisor: Dr. Lei Dong, Associate Chief Physician*

#### Contribution:

- Retrieved genetic databases for the sequence of a specific Myd88 point mutation; designed TaqMan probes, quality control plasmids, and six PCR primer pairs in Amplification Refractory Mutation System (ARMS) method for the detection of Myd88 point mutation
- Performed qRT-PCR to detect diluted plasmids; verified the eligibility of each primer pair
- Determined the optimal initial concentration of ARMS primer pair

## **Microfluidic Chip Design for Early Detection of Breast Cancer in Digital PCR Method**

*Shanghai Jiao Tong University School of Biomedical Engineering*

**May 2017-Dec. 2018**

*Advisor: Dr. Xianting Ding, Professor*

### **Contribution:**

- Wrote research proposal, mainly tasked with the study design
- Compared several detection methodologies and suggested to combine microdroplet chip with digital PCR
- Improved the existing chip design and drew the sketch for chip fabrication
- Finished two literature reviews

### **Conference Presentations:**

- Woldetsadik Y, **Wang A**, Perez D, Cardenas-Garcia S, Klein SL. Characterizing sex differences in Influenza B virus pathogenesis in C57BL/6 mice. Centers of Excellence for Influenza Research and Surveillance (CEIRS) (2021) **\*Poster awarded\***
- **Wang A**, Cardenas-Garcia S, Rajao D, Perez D Klein SL. The effect of biological sex on influenza B virus pathogenesis in C57BL/6 mice. American Society for Virology (2021) **\*Poster Presentation\***

### **Peer Reviewed Publications:**

- **Wang A**, Abdulla A, Ding X. Microdroplets-on-chip: A review. Proceedings of the Institution of Mechanical Engineers, Part H: Journal of Engineering in Medicine. 2019;233(7):683-694.  
doi:10.1177/0954411919850912

### **Ad hoc peer review:**

- Journal of Virology: Defective NKp46 recognition and elimination of influenza B viruses (2020)
- EBioMedicine: Shorter androgen receptor polyQ alleles protect against life-threatening COVID-19 disease in males (2020)
- Scientific Report: Male to female ratio of influenza morbidity switches between children and adults (2020)

## **INTERSHIPS**

---

### **Roche Diagnostics, Shanghai**

**Nov. 2018-Jun. 2019**

*Assistant to Bidding Operation Team*

- Established and optimized the database of 200 products
- Assisted with the confirmation of actions for identified tenders in the first and second quarter of 2019, followed up bidding results, and conducted bidding data analysis

### **Obstetrics and Gynecology Hospital of Fudan University**

**May 2018-Nov. 2018**

*Intern in Clinical Lab*

- Outpatient Care: took charge of finger blood routine and urine routine examinations
- Blood Specimen Lab: collected and pre-processed the clinical specimens; read blood smears; used automatic instruments to perform immunological and biochemical examination, issued test reports and provided consultations for physicians; performed quality control and maintenance for instruments
- Microbe Lab: took charge of specimen inoculation and chlamydia examination

### **Shanghai Ruijin Hospital**

**Jul. 2017-Aug. 2017**

*Intern in Clinical Lab*

- Responsible for specimen collection and pretreatment, finger blood collection
- Used automatic instruments to perform biochemical examination, nearly 1000 specimens daily

## SKILLS

---

### **Experimental Skills**

- Blood smear staining and morphology examination
- Bacteria and cell cultivation; virus propagation and titration
- Animal modeling and surgery
- Neutralizing assay, ELISA

### **Software**

- Stata 15, R, Primer 5, Prism, Microsoft Office
